Abstract

Read-Copy Update (RCU) — это высокопроизводительный масштабируемый механизм синхронизации ядра операционной системы Linux, который позволяет выполнять нетребовательные к ресурсам запросы на чтение данных вместе с запросами на их изменение. Реализация качественного RCU для многоядерных систем является весьма сложной задачей. Учитывая распространенность Linux, даже самая редкая ошибка исходного кода реализации будет проявлятся недопустимо часто. В связи с этим, строгая валидация сложных сценариев поведения RCU является критически важной. В связи с тем, что исчерпывающее тестирование данного механизма невозможно из-за экпоненциального роста числа сценариев тестирования, имеет смысл использовать метод формальной верификации.

Следует отметить, что прошлые попытки верификации RCU были направлены либо на более простые реализации, либо использовали языки моделирования, что требует процесса ручного перевода исходного текста ядра, который также подвержен ошибкам. Кроме этого, подобный перевод придется выполнять слишком часто, поскольку в реализацию RCU Linux регулярно вносятся правки. В этой статье мы опишем реализацию Tree RCU в ядре Linux, затем рассмотрим подход к построению модели верификации напрямую из исходного кода реализации и использованию верификатора CBMC для проверки ее инвариантов. По нашим сведениям, это первая попытка верификации существенной части исходного кода RCU и важный шаг на пути интеграции процедуры формальной верификации в набор регрессионных тестов ядра Linux.

Keywords Верификация программного обеспечения, Параллельные вычисления, Read-Copy Update, ядро Linux

1. Введение

Ядро операционной системы Linux широко используется во множестве вычислительных платформ, включая сервера, встроенные системы, бытовую технику и мобильные устройства (смартфоны). В течение последних 25 лет в ядре Linux было реализовано множество технологий, одной из которых является Read-Copy Update (RCU) [**?**].

RCU — это механизм синхронизации, который может исопльзоваться взамен блокировок чтения-записи в тех случаях, когда число запросов на чтение значительно больше. Он позволяет выполнять нетребовательные к ресурсам запросы на чтение данных вместе с запросами на их изменение. Качественные реализации RCU для многоядерных систем должны обладать такими качествами, как отличная масштабируемость, высокая пропускная способность, низкие задержки, умеренный расход памяти, низкое энергопотребление и поддерживать «hotplug» операции процессора. В связи с этим реализация должна избегать кэш-промахов, избыточного использования блокировок, общих переменных, а также атомарных «read-modify-write» и «memory-barrier» инструкций. Наконец, реализация должна поддерживать все многообразие целевых платформ и сценариев использования Linux [?].

В настоящее время RCU широко используется в сетевой, файловой подсистемах ядра Linux, а также в подсистеме работы с устройствами [? ?]. На данный момент в мире насчитывается более 75 миллионов Linux-серверов и 1.4 миллирдов мобильных Android-устройств. На практике это означает, что даже самая редкая ошибка исходного кода реализации будет проявлятся недопустимо часто. В связи с этим, строгая валидация сложных сценариев поведения RCU является критически важной. В связи с тем, что исчерпывающее тестирование данного механизма невозможно из-за экпоненциального роста числа сценариев тестирования, имеет смысл использовать метод формальной верификации.

Основные усилия, направленные с верификацией многопоточного программного обеспечения, основаны на на тестировании, но, к сожалению, на данный момент не существует эффективной методики тестирования такого ПО, способной проверить все возможные сценарии. Более того, некоторые ошибки, которые обнаруживаются в ходе тестирования, могут быть трудными для повторного воспроизведения, отладки и исправления. Многопоточная сущность RCU и огромное пространство возможных сценариев тестирования наводят на мысль об использовании методов формальной верификации, в частности, верификации моделей [?].

Следует отметить, что формальные методы уже применялись ранее для верификации некоторых частей дизайна RCU, например Tiny RCU [?], userspace RCU [?], sysidle [?] и взаимодействия между dyntick-idle и немаскируемыми прерываениями (NMIs) [?]. Но эти попытки были направлены либо на верификацию примитивных реализаций RCU для одноядерных систем (Tiny RCU), либо использовали специализированные языки описания моделей, такие, как Promela [?]. Несмотря на то, что данные языки имеют ряд преимуществ, основных недостатком их использования в контексте ядра Linux является сложность ручной трансляции исходного кода. Иные исследователи использовали аппарат формальной логики для верификации простых реализаций RCU [? ?]. Несмотря на то, что данный подход является весьма интересным, он требует большего количества работы, нежели трансляция исходного кода.

Более того, цикл разработки ядра Linux составляет около 60 дней, и в течение каждого из них вносятся правки в RCU. В связи с этим всякий ручной труд по верификации должен будет повторяться шесть раз в год, чтобы формальные модели верификации RCU оставались актуальными. Из этого следует, что для того, чтобы процесс формальной верификации RCU мог быть включен в набор регрессинных тестов, используемые в нем методы должны быть автоматизируемыми и масштабируемыми. В этой статье описывается процесс построения модели верификации напрямую из исходного кода реализации RCU в Linux и использование C Bounded Model Checker (CBMC) [?] для проверки ее инвариантных свойств. По нашим сведениям, это первая попытка автоматизированной верификации существенной части исходного кода RCU и важный шаг на пути интеграции процедуры формальной верификации в набор регрессионных тестов ядра Linux.

2. Background

2.1 Что такое RCU?

Read-copy update (RCU) — это механизм синхронизации, часто используемый вместо блокировок чтения-записи. RCU позволяет потокам-читателям выполняться одновременно с потоками-писателями, избегая использования блокировок чтения за счет управления жизненными циклами множества версий объекта чтения. В частности, данный механизм следит, чтобы объект, к которому обращается поток-читатель, не был удален в течение некоторого *grace*-периода после его изменения потоком-писателем. Суть метода состоит в том, чтобы разделить процесс обновления объекта на фазу удаления и освобождения, между которыми находится некоторый промежуток времени — *grace*-период [?]. В ходе фазы удаления выполнятеся удаление ссылок на обьекты, доступных для потоков-читетелей, сопровождающееся, возможно, заменой их новыми версиями.

Современные процессоры гарантируют, что операции чтения одичночных выравненных указателей являются атомарными, поэтому потоки-читатели могут получить доступ исключительно либо к старой или новой версии объекта чтения. Atomic-write semantics позволяет выполнять атомарные вставки, удаления и замены в связанных структурах данных. Это, в свою очередь, позволяет потокам-читателям отказаться от использования «дорогих» атомарных операций, избавиться от барьеров памяти и связанных с ними промахов кэша. Действительно, в самых оптимизированных конфигурациях Linux RCU, потоки-читатели могут выполнять точно такую же последовательность инструкций, какая использовалась бы в их однопоточной реализации, что обеспечивает их отличную производительность и масштабируемость.

Как показано на рисунке 1, *grace*-периоды в действительности нужны только для тех потоков-читателей, время выполнения которых накладывается на фазу удаления. Те из них, которые выполняются после удаления, не могут удерживать ссылки на удаленные объекты и поэтому не могут быть прерваны в ходе фазы освобождения.

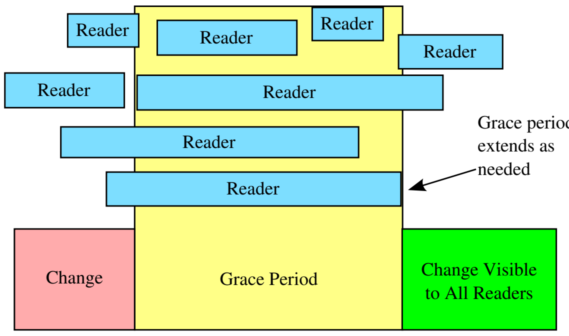

Рис. 1: RCU Concepts

2.2 Программный интерфейс RCU

Программный интерфейс RCU достаточно мал и состоит всего из пяти примитивов: `rcu_read_lock()`, `rcu_read_unlock()`, `synchronize_rcu()`, `rcu_assign_pointer()`, and `rcu_dereference()` [?].

Критическая секция RCU-читателя начинается с `rcu_read_lock()` и заканчивается соответсвующим `rcu_read_unlock()`. Вложенные критические секции чтения объединяются. Внутри критической секции запрещается блокирование данного потока. Данные, чтение которых осуществляется доступ внутри критической секции RCU, будут доступны до её окончания.

Функция `synchronize_rcu()` соответсвует окончанию выполнения кода, обновляющего значение объекта, тем самым сигнализируя о начале фазы освобождения. Она блокирует поток-писатель до тех пор, пока все потоки-читатели не выйдут из своих критических RCU-секций. Отметим, что `synchronize_rcu()` не ожидает окончания критических секций, вход в которые был осуществлен позже.

Рассмотрим пример, приведенный на рисунке 2. Если вход в критическую секцию чтения функции `rcu_reader()` выполнится до вызова `synchronize_rcu()` в `rcu_updater()`, то выход из ней должен быть совершен до возврата из `synchronize_rcu()`, чтобы значение переменной `r2` было равно 0. Если же вход в неё произойдет после возврата из `synchronize_rcu()`, то значение `r1` будет равным 1.

Наконец, для присвоения нового значения указателю, защищенному RCU, потоки-писатели должны использовать `rcu_assign_pointer()`, которая возвращает новое значение. RCU-читатели могут использовать `rcu_dereference()` для чтения указателя, защищенного RCU, который впоследствии может быть безопасно разыменован. Возвращаемое ею значение является корректным лишь внутри критической секции. Функции `rcu_assign_pointer()` и `rcu_dereference()` используются в паре для того, чтобы убедиться, что если данный поток-читатель разыменовывает защищенный указатель на только что вставленный объект, операция разыменования вернет корректное значение, а не недоинициализированный мусор.

```
int x = 0;
int y = 0;
int r1, r2;

void rcu_reader(void) {
  rcu_read_lock();
  r1 = x;
  r2 = y;
  rcu_read_unlock();
}

void rcu_updater(void) {
  x = 1;
  synchronize_rcu();
  y = 1;
}

...

// after both rcu_reader()
// and rcu_updater() return
assert(r2 == 0 || r1 == 1);
```

Рис. 2: Verifying RCU Grace Periods

3. Implementation of Tree RCU

The primary advantage of RCU is that it is able to wait for an arbitrarily large number of readers to finish without keeping track every single one of them. The number of readers can be large (up to the number of CPUs in non-preemptible implementations and up to the number of tasks in preemptible implementations). Although RCU's read-side primitives enjoy excellent performance and scalability, update-side primitives must defer the reclamation phase till all pre-existing readers have completed, either by blocking or by registering a callback that is invoked after a grace period. The performance and scalability of RCU relies on efficient mechanisms to detect when a grace period has completed. For example, a simplistic RCU implementation might require each CPU to acquire a global lock during each grace period, but this would severely limit performance and scalability. Such an implementation would be quite unlikely to scale beyond a few hundred CPUs. This is woefully insufficient because Linux runs on systems with thousands of CPUs. This has motivated the creation of Tree RCU.

3.1 Overview

We focus on the "vanilla" RCU API in a non-preemptible build of the Linux kernel, specifically on the `rcu_read_lock()`, `rcu_read_unlock()`, and `synchronize_rcu()` primitives. The key idea is that RCU read-side primitives are confined to kernel code and, in non-preemptible implementations, do not block. Thus, when a

CPU is blocking, in the idle loop, or running in user mode, all RCU read-side critical sections that were previously running on that CPU must have finished. Each of these states is therefore called a *quiescent state*. After each CPU has passed through a quiescent state, the corresponding RCU grace period ends. The key challenge is to determine when all necessary quiescent states have completed for a given grace period—and to do so with excellent performance and scalability.

For example, if RCU used a single data structure to record each CPU's quiescent states, the result would be extreme lock contention on large systems, in turn resulting in poor performance and abysmal scalability. Tree RCU therefore instead uses a tree hierarchy of data structures, each leaf of which records quiescent states of a single CPU and propagates the information up to the root. When the root is reached, a grace period has ended. Then the grace-period information is propagated down from the root to the leaves of the tree. Shortly after the leaf data structure of a CPU receives this information, `synchronize_rcu()` will return.

In the remainder of this section, we discuss the implementation of the non-preemptible Tree RCU in the Linux kernel version 4.3.6. We first briefly discuss the implementation of read/write-side primitives. We then explain Tree RCU's hierarchical data structure which records quiescent states while maintaining bounded lock contention. Finally, we discuss how RCU uses this data structure to detect quiescent states and grace periods without individually tracking readers.

3.2 Read/Write-Side Primitives

In a non-preemptible kernel, any region of kernel code that does not voluntarily block is implicitly an RCU read-side critical section. Therefore, the implementations of `rcu_read_lock()` and `rcu_read_unlock()` need do nothing at all, and in fact in production kernel builds that do not have debugging enabled, these two primitives have absolutely no effect on code generation.

In the common case where there are multiple CPUs running, the update-side primitive `synchronize_rcu()` calls `wait_rcu_gp()`, which is an internal function that uses a callback mechanism to invoke `wakeme_after_rcu()` at the end of some later grace period. As its name suggests, `wakeme_after_rcu()` function wakes up `wait_rcu_gp()`, which returns, in turn allowing `synchronize_rcu()` to return control to its caller.

3.3 Data Structures of Tree RCU

RCU's global state is recorded in the `rcu_state` structure, which consists of a tree of `rcu_node` structures with a child count of up to 64 (32 in a 32-bit system). Every leaf node can have at most 64 `rcu_data` structures (again 32 on a 32-bit system), each representing a single CPU, as illustrated in Figure 3. Each `rcu_data` structure

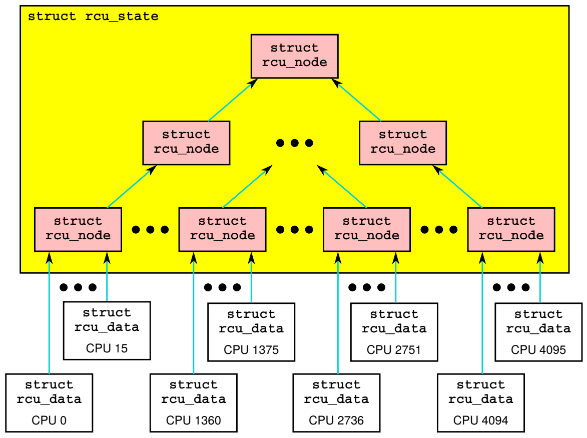

Рис. 3: Tree RCU Hierarchy

records its CPU's quiescent states, and the `rcu_node` tree propagates these states up to the root, and then propagates grace-period information back down to the leaves. Quiescent-state information does not propagate upwards from a given node until a quiescent state has been reported by each CPU covered by the subtree headed by that node. This propagation scheme dramatically reduces the lock contention experienced by the upper levels of the tree. For example, consider a default `rcu_node` tree for a 4,096-CPU system, which will have have 256 leaf nodes, four internal nodes, and one root node. During a given grace period, each CPU will report its quiescent states to its leaf node, but there will only be 16 CPUs contending for each of those 256 leaf nodes. Only 256 of the CPUs will report quiescent states to the internal nodes, with only 64 CPUs contending for each of the four internal nodes. Only four CPUs will report quiescent states to the root node, resulting in extremely low contention on the root node's lock, so that contention on any given `rcu_node` structure is sharply bounded even in very large configurations. The current RCU implementation in the Linux kernel supports up to a four-level tree, and thus in total $64^4 = 16,777,216$ CPUs in a 64 bit machine.[1]

3.3.1 `rcu_state` Structure

Each flavor of RCU has its own global `rcu_state` structure. The `rcu_state` structure includes a array of `rcu_node` structures organized as a tree `struct rcu_node node[NUM_RCU_NODES]`, with `rcu_data` structures connected to the leaves. Given this organization, a breadth-first traversal is simply a linear scan of the array. Another array `struct rcu_node *level[NUM_RCU_LVLS]` is used to point to the left-most node at each level of the tree, as shown in Figure 4.

[1] Four-level trees are only used in stress testing, but three-level trees are used in production by 4096-CPU systems.

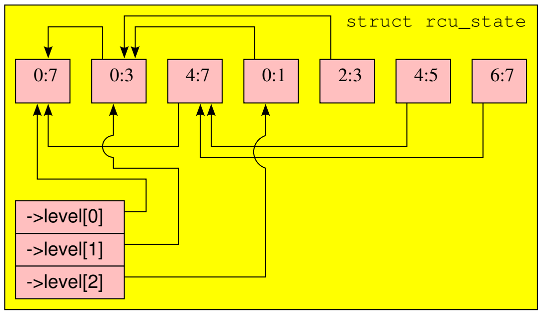

Рис. 4: Array Representation for a Tree of `rcu_node` Structures

The `rcu_state` structure uses **`unsigned long`** fields `->gpnum` and `->completed` to track RCU's grace periods. The `->gpnum` field records the most recently started grace period, whereas `->completed` records the most recently ended grace period. If the two numbers are equal, then corresponding flavor of RCU is idle. If `gpnum` is one greater than `completed`, then RCU is in the middle of a grace period. All other combinations are invalid.

3.3.2 `rcu_node` Structure

The tree of `rcu_node` structures records and propagates quiescent-state information from the leaves to the root, and also propagates grace-period information from the root to the leaves. The `rcu_node` structure has a spinlock `->lock` to protect its fields. The `->parent` field references the parent `rcu_node` structure, and is `NULL` for the root. The `->level` field indicates the level in the tree, counting from zero at the root. The `->grpmask` field identifies this node's bit in the `->qsmask` field of its parent. The `->grplo` and `->grphi` fields indicates the lowest and highest numbered CPU that are covered by this `rcu_node` structure, respectively.

The `->qsmask` field indicates which of this node's children still need to report quiescent states for the current grace period. As with `rcu_state`, the `rcu_node` structure has `->gpnum` and `->completed` fields that have values identical to those of the enclosing `rcu_state` structure, except at the beginnings and ends of grace periods when the new values are propagated down the tree. Each of these fields can be smaller than its `rcu_state` counterpart by at most one.

3.3.3 `rcu_data` structure

The `rcu_data` structure detects quiescent states and handles RCU callbacks for the corresponding CPU. The structure is accessed primarily from the corresponding CPU, thus avoiding synchronization overhead. As with the `rcu_state` structure, different flavors of RCU maintain their own per-CPU `rcu_data` structures. The `->cpu` field identifies the corresponding CPU, the `->rsp` field references the corresponding `rcu_state` structure, and

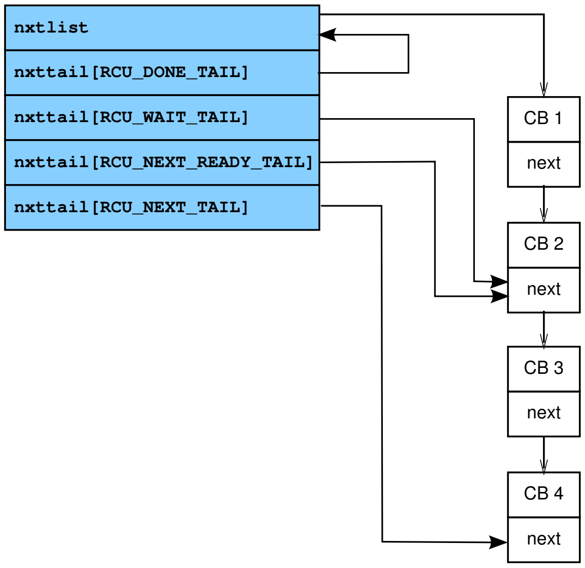

Рис. 5: Callback Queuing in `rcu_data`

the `->mynode` field references the corresponding leaf `rcu_node` structure. The `->grpmask` field identifies this `rcu_data` structure's bit in the `->qsmask` field of its leaf `rcu_node` structure.

The `rcu_data` structure's `->qs_pending` field indicates that RCU needs a quiescent state from the corresponding CPU, and the `->passed_quiesce` indicates that the CPU has already passed through a quiescent state. The `rcu_data` also has `->gpnum` and `->completed` fields, which can lag arbitrarily behind their counterparts in the `rcu_state` and `rcu_node` structures on idle CPUs. However, on the non-idle CPUs that are the focus of this paper, they can lag at most one grace period behind their leaf `rcu_node` counterparts.

The `rcu_state` structure's `->gpnum` and `->completed` fields represent the most current values, and are tracked closely by those of the `rcu_node` structure, which allows the `->gpnum` and `->completed` fields in the `rcu_data` structures to be are compared against their counterparts in the corresponding leaf `rcu_node` to detect a new grace period. This scheme allows CPUs to detect beginnings and ends of grace periods without incurring lock- or memory-contention penalties. The `rcu_data` structure manages RCU callbacks using a four-segment list [?].

3.3.4 RCU Callbacks

The `rcu_data` structure manages RCU callbacks using a `->nxtlist` pointer tracking the head of the list and an array of `->nxttail[]` tail pointers that form a four-segment list of callbacks [?], with each element of the `->nxttail[]` array referencing the tail of the corresponding segment, as shown in Figure 5. The segment ending with `->nxttail[RCU_DONE_TAIL]` (the "`RCU_DONE_TAIL` segment") contains callbacks handled by a prior grace period that are therefore ready to be invoked. The RCU_WAIT_TAIL and RCU_NEXT_READY_TAIL segments contain callbacks waiting for the current and the next grace period, respectively. Finally, the RCU_NEXT_TAIL segment contains callbacks that are not yet associated with any grace period. The ->qlen field counts the total number of callbacks, and the ->blimit field specifies the maximum number of RCU callbacks that may be invoked at a given time, thus limiting response-time degradation due to long lists of callbacks.[2]

Back in Figure 5, the ->nxttail[RCU_DONE_TAIL] array element references ->nxtlist, which means none of the callbacks are ready to invoke. The ->nxttail[RCU_WAIT_TAIL] element references callback 2's ->next pointer, meaning that callbacks CB 1 and CB 2 are waiting for the current grace period. The ->nxttail[RCU_NEXT_READY_TAIL] element references that same ->next pointer, meaning that no callbacks are waiting for the next grace period. Finally, the callbacks between the ->nxttail[RCU_NEXT_READY_TAIL] and ->nxttail[RCU_NEXT_TAIL] elements (CB 3 and CB 4) are not yet assigned to a specific grace period. The ->nxttail[RCU_NEXT_TAIL] element always references either the last callback or, when the entire list is empty, ->nxtlist.

Cache locality is promoted by invoking callbacks on the CPU that registered them. For example, RCU's update-side primitive synchronize_rcu() appends callback wakeme_after_rcu() to the end of the ->nxttail[RCU_NEXT_TAIL] list in the current CPU (Section **??**). They are advanced one segment towards the head of the list (via rcu_advance_cbs()) when the CPU detects the current grace period has ended, which is indicated by the ->completed field of the CPU's rcu_data structure being one smaller than its counterpart in the corresponding leaf rcu_node structure. The CPU also periodically merges the RCU_NEXT_TAIL segment into the RCU_NEXT_READY_TAIL segment by calling rcu_accelerate_cbs(). In a few special cases, the CPU merges the RCU_NEXT_TAIL segment into the RCU_WAIT_TAIL segment, bypassing the RCU_NEXT_TAIL segment. This optimization applies when the CPU is starting a new grace period. It does *not* apply when a CPU notices a new grace period because that grace period might well have started before the callbacks were added to the RCU_NEXT_TAIL segment. This is a deliberate design choice: It is more important for the CPUs to operate independently (thus avoiding contention and synchronization overhead) than it is to decrease grace-period latencies. In those rare occasions where low grace-period latency is important, the synchronize_rcu_expedited() should be used. This function has the same semantics as does synchronize_rcu(), but trades off efficiency optimizations in favor of reduced latency.

Each RCU callbacks is an rcu_head structure which has a ->next field that points to the next callback on the list and a ->func field that references the function to be invoked at the end of an upcoming grace period.

3.4 Quiescent State Detection

RCU has to wait until all pre-existing read-side critical sections have finished before it can safely allow a grace period to end. The performance and scalability of RCU rely on its ability to efficiently detect quiescent states and determine whether the set of quiescent states detected thus far allows the grace period to end. If each CPU (or, in the case of preemptible RCU, each task) has passed through a quiescent state, a grace period has elapsed.

The non-preemptible RCU-sched flavor's quiescent states apply to CPUs, and are user-space execution, context switch, idle, and offline state. Therefore, RCU-sched only needs to track tasks and interrupt handlers that are actually running because blocked and preempted tasks are always in quiescent states. Thus, RCU-sched needs only track CPU states.

3.4.1 Scheduling-Clock Interrupt

The rcu_check_callbacks() is invoked from the scheduling-clock interrupt handler, which allows RCU to periodically check whether a given busy CPU is in the user-mode or idle-loop quiescent states. If the CPU is in one of these quiescent states, rcu_check_callbacks() invokes rcu_sched_qs(), which sets the per-CPU rcu_sched_data.passed_quiesce fields to 1.

The rcu_check_callbacks() function invokes rcu_pending() to determine whether a recent event or current condition means that RCU requires attention from this CPU. If so, rcu_check_callbacks() invokes raise_softirq(), which will cause rcu_process_callbacks() to be invoked once the CPU reaches a state where it is safe to do so (roughly speaking, once the CPU has interrupts, preemption, and bottom halves enabled). This function is discussed in detail in Section 3.5.

3.4.2 Context-Switch Handling

The context-switch quiescent state is recorded by invoking rcu_note_context_**switch**() from __schedule() (and, for the benefit of virtualization, also from rcu_virt_note_context_**switch**()). The rcu_note_context_**switch**() function invokes rcu_sched_qs() to inform RCU of the context switch, which is a quiescent state of the CPU.

3.5 Grace Period Detection

Once each CPU has passed through a quiescent state, a grace period for RCU has completed. As discussed in Section 3.3, Tree-RCU uses a hierarchy of rcu_node

[2] Workloads requiring aggressive real-time guarantees should use callback offloading, which is outside of the scope of this paper.

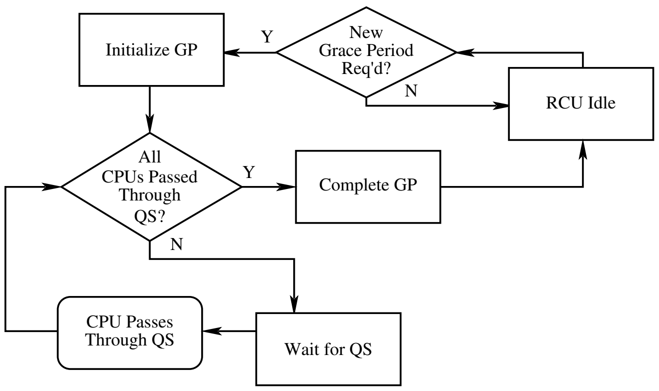

Рис. 6: Grace-Period Detection State Diagram

structures to manage quiescent state and grace period information. Quiescent-state information is passed up the tree from the leaf per-CPU `rcu_data` structures. Grace-period information is passed down from the root. We focus on grace-period detection for busy CPUs, as illustrated in Figure 6.

3.5.1 Softirq Handler for RCU

RCU's busy-CPU grace period detection relies on the `RCU_SOFTIRQ` handler function `rcu_process_callbacks()`, which is scheduled from the scheduling-clock interrupt. This function first calls `rcu_check_quiescent_state()` to report recent quiescent states on the current CPU. Then `rcu_process_callbacks()` starts a new grace period if needed, and finally calls `invoke_rcu_callbacks()` to invoke any callbacks whose grace period has already elapsed.

Function `rcu_check_quiescent_state()` first invokes `note_gp_changes()` to update the CPU-local `rcu_data` structure to record the end of previous grace periods and the beginning of new grace periods. Any new values for these fields are copied from the leaf `rcu_node` structure to the `rcu_data` structure. If an old grace period has ended, `rcu_advance_cbs()` is invoked to advance all callbacks, otherwise, `rcu_accelerate_cbs()` is invoked to assign a grace period to any recently arrived callbacks. If a new grace period has started, `->passed_quiesce` is set to zero, and if in addition RCU is waiting for a quiescent state from this CPU, `->qs_pending` is set to one, so that a new quiescent state will be detected for the new grace period.

Next, `rcu_check_quiescent_state()` checks whether `->qs_pending` indicates that RCU needs a quiescent state from this CPU. If so, it checks whether `->passed_quiesce` indicates that this CPU has in fact passed through a quiescent state. If so, it invokes `rcu_report_qs_rdp()` to report that quiescent state up the combining tree.

The `rcu_report_qs_rdp()` function first verifies that the CPU has in fact detected a legitimate quiescent state for the current grace period, and under the protection of the leaf `rcu_node` structure's `->lock`. If not, it resets quiescent-state detection and returns, thus ignoring any redundant quiescent states belonging to some earlier grace period. Otherwise, if the `->qsmask` field indicates that RCU needs to report a quiescent state from this CPU, `rcu_accelerate_cbs()` is invoked to assign a grace-period number to any new callbacks, and then `rcu_report_qs_rnp()` is invoked to report the quiescent state to the `rcu_node` combining tree.

The `rcu_report_qs_rnp()` function traverses up the `rcu_node` tree, at each level holding the `rcu_node` structure's `->lock`. At any level, if the child structure's `->qsmask` bit is already clear, or if the `->gpnum` changes, traversal stops. Otherwise, the child structure's bit is cleared from `->qsmask`, after which, if `->qsmask` is non-zero, traversal stops. Otherwise, traversal proceeds on to the parent `rcu_node` structure. Once the root is reached, traversal stops and `rcu_report_qs_rsp()` is invoked to awaken the grace-period kthread (kernel thread). The grace-period kthread will then clean up after the now-ended grace period, and, if needed, start a new one.

3.5.2 Grace-Period Kernel Thread

The RCU grace-period kthread invokes `rcu_gp_kthread()`, which contains an infinite loop that initializes, waits for, and cleans up after each grace period.

When no grace period is required, the grace-period kthread sets its `rcu_state` structure's `->flags` field to `RCU_GP_WAIT_GPS`, and then waits within an inner infinite loop for that structure's `->gp_state` field to be set. Once set, `rcu_gp_kthread()` invokes `rcu_gp_init()` to initialize a new grace period, which rechecks the `->gp_state` field under the root `rcu_node` structure's `->lock`. If the field is no longer set, `rcu_gp_init()` returns zero. Otherwise, it increments `rsp->gpnum` by 1 to record a new grace period number. Finally, it performs a breadth-first traversal of the `rcu_node` structures in the combining tree. For each `rcu_node` structure `rnp`, we set the `rnp->qsmask` to indicate which children must report quiescent states for the new grace period (Section 3.3.2), and set `rnp->gpnum` and `rnp->completed` to their `rcu_state` counterparts. If the `rcu_node` structure `rnp` is the parent of the current CPU's `rcu_data`, we invoke `__note_gp_changes()` to set up the CPU-local `rcu_data` state. Other CPUs will invoke `__note_gp_changes()` after their next scheduling-clock interrupt.

To clean up after a grace period, `rcu_gp_kthread()` calls `rcu_gp_cleanup()` after setting the `rcu_state` field `rsp->gp_state` to `RCU_GP_CLEANUP`. After the function returns, `rsp->gp_state` is set to `RCU_GP_CLEANED` to record the end of the old grace period.

Function rcu_gp_cleanup() performs a breadth-first traversal of rcu_node combining-tree. It first sets each rcu_node structure's ->completed field to the rcu_state structure's ->gpnum field. It then updates the current CPU's CPU-local rcu_data structure by calling __note_gp_changes(). For other CPUs, the update will take place when they handle the scheduling-clock interrupts, in a fashion similar to rcu_gp_init(). After the traversal, it marks the completion of the grace period by setting the rcu_state structure's ->completed field to that structure's ->gpnum field, and invokes rcu_advance_cbs() to advance callbacks. Finally, if another grace period is needed, we set rsp->gp_flags to RCU_GP_FLAG_INIT. Then in the next iteration of the outer loop, the grace-period kthread will initialize a new grace period as discussed above.

4. Verification Scenario

We use the example in Figure 2 to demonstrate how the different components of Tree RCU work together to guarantee that all pre-existing read-side critical sections finish before RCU allows a grace period to end. This example will drive the verification, which will check for violations of the assertion at this end of the code.

We focus on the implementation of the non-preemptible RCU-sched flavor. We further assume there are only two CPUs, and that CPU 0 executes function rcu_reader() and CPU 1 executes rcu_updater(). When the system boots, the Linux kernel calls rcu_init() to initialize RCU, which includes constructing the combining tree of rcu_node and rcu_data structures via rcu_init_geometry() and initializing the fields of the nodes in the tree for each RCU flavor via rcu_init_one(). In our example it will be a one-level tree that has one rcu_node structure as root and two children that are rcu_data structures for each CPU. Function rcu_spawn_gp_kthread() is also called to initialize and spawn the RCU grace-period kthread for each RCU flavor.

Referring again to Figure 2, suppose that rcu_reader() begins execution on CPU 0 while rcu_updater() concurrently sets x to 1 and then invokes synchronize_rcu() on CPU 1. As discussed in Section 3.2, synchronize_rcu() invokes wait_rcu_gp(), which in turn registers an RCU callback that will invoke wakeme_after_rcu() some time after rcu_reader() exits its critical section.

However, this critical-section exit has no immediate effect. Instead, a later context switch will invoke rcu_note_context_**switch**(), which in turn invokes rcu_sched_qs(), recording the quiescent state in the CPU's rcu_sched_data structure's ->passed_quiesce field. Later, a scheduling-clock interrupt will invoke rcu_check_callbacks(), which calls rcu_pending() and notes that the ->passed_quiesce field is set. This will cause rcu_pending() to return true, which in turn causes rcu_check_callbacks() to invoke rcu_process_callbacks(). In its turn, rcu_process_callbacks() will invoke raise_softirq(RCU_SOFTIRQ), which, once the CPU has interrupts, preemption, and bottom halves enabled, calls rcu_process_callbacks().

As discussed in Section 3.5.1, RCU's softirq handler function rcu_process_callbacks() first calls rcu_check_quiescent_state() to report any recent quiescent states on the current CPU (CPU 0). Then it checks whether the CPU 0 has passed a quiescent state. Since a quiescent state has been recorded for CPU 0, rcu_report_qs_rnp() is invoked to traversal up the combining tree. It clears the first bit of the root rcu_node structure's qsmask field (recall that the RCU combining tree has only one level). Since the second bit for CPU 1 has not been cleared, the function returns.

Since synchronize_rcu() blocks in CPU 1, it will result in a context switch. This triggers a sequence of events similar to that described above for CPU 1, which results in the clearing of the second bit of the root rcu_node structure's ->qs_mask field, the value of which is now 0, indicating the end of the current grace period. CPU 1 therefore invokes rcu_report_qs_rsp() to awaken the grace-period kthread, which will clean up the ended grace period, and, if needed, start a new one (Section 3.5.2).

Lastly, rcu_process_callbacks() calls invoke_rcu_callbacks() to invoke any callbacks whose grace period has already elapsed, for example, wakeme_after_rcu(), which will allow synchronize_rcu() to return.

5. Modeling RCU for CBMC

The C Bounded Model Checker (CBMC)[3] is a program analyzer that implements bit-precise bounded model checking for C programs [?]. CBMC can demonstrate violation of assertions in C programs, or prove their safety under a given loop unwinding bound. It translates an input C program into a formula, which is then passed to a modern SAT or SMT solver together with a constraint that specifies the set of error states. If the solver determines the formula to be satisfiable, an error trace giving the exact sequence of events is extracted from the satisfying assignment. Recently, support has been added for verifying concurrent programs over a wide range of memory models, including SC, TSO, and PSO [?].

In the remainder of this section we describe how to construct a model from the source code of the Tree RCU implementation in the Linux kernel version 4.3.6, which can be verified by CBMC. Model construction entailed stubbing out calls to other parts of the kernel, removing irrelevant functionality (such as idle-CPU detection), removing irrelevant data (such as statistics), and adding preprocessor

[3] http://www.cprover.org/cbmc/

directives to conditionally inject bugs (described in Section 6.1). The Linux kernel environment and the majority of these changes to the source code are made through macros in separate files that can be reused across different versions of the Tree RCU implementation. The biggest change in the source files is to use arrays to model per-CPU data, which could potentially be scripted. The resulting model is C code with assertions that can be also run as a user program, which provides important validation of the model itself.

Initialization

Our model first invokes `rcu_init()` which in turn invokes: (1) `rcu_init_geometry()` to compute the `rcu_node` tree geometry; (2) `rcu_init_one` to initialize the `rcu_state` structure; (3) `rcu_cpu_notify()` to initialize each CPU's `rcu_data` structure. This boot initialization tunes the data-structure configuration to match that of the specific hardware at hand. For example, a large-system tree might resemble Figure 3, while a small configuration has a single `rcu_node` "tree". The model then calls `rcu_spawn_gp_kthread()` to spawn the grace-period kthreads discussed below.

Per-CPU Variables and State

RCU uses per-CPU data to provide cache locality and to reduce contention and synchronization overhead. For example, the per-CPU structure `rcu_data` records quiescent states and handles RCU callbacks (Section 3.3.3). We model this per-CPU data as an array, indexed by CPU ID.

It is also necessary to model per-CPU state, including the currently running task and whether or not interrupts are enabled. Identifying the running task requires a (trivial) model of the Linux-kernel scheduler, which uses an integer array `cpu_lock`, indexed by CPU ID. Each element of this array models an exclusive lock. When a task schedules on a given CPU, it acquires the corresponding CPU lock, and releases it when scheduling away. We currently do not model preemption, so need model only voluntary context switches.

A pair of integer arrays `local_irq_depth` and `irq_lock` is used to model CPUs enabling and disabling interrupts. Both arrays are indexed by CPU ID, with the first recording each CPU's interrupt-disable nesting depth and the second recording whether or not interrupts are disabled.

Update-Side API `synchronize_sched()`

Because our model omits CPU hotplug and callback handling, we cannot use Tree RCU's normal callback mechanisms to detect the end of a grace period. We therefore use a global variable `wait_rcu_gp_flag`, which is initialized to 1 in `wait_rcu_gp()` before the grace period. Because `wait_rcu_gp()` blocks, it can result in a context switch, the model invokes `rcu_note_context_switch()`, followed by a call to `rcu_process_callbacks()` to inform RCU of the resulting quiescent state. When the resulting quiescent states propagate to the root of the combining tree, the grace-period kthread is awakened. This kthread then invokes `rcu_gp_cleanup()`, the modeling of which is described below. Then `rcu_gp_cleanup()` calls `rcu_advance_cbs()`, which invokes `pass_rcu_gp()` to clear the `wait_rcu_gp_flag` flag. The `__CPROVER_assume(wait_rcu_gp_flag == 0)` in `wait_rcu_gp()` prevents CBMC from continuing execution until `wait_rcu_gp_flag` is equal to 0, thus modeling the needed grace-period wait.

Scheduling-Clock Interrupt and Context Switch

The `rcu_check_callbacks()` function detects idle execution, usermode execution, and to invoke RCU core processing in response to state changes. Because we model neither idle nor usermode execution, the only state changes are quiescent states and the beginnings and ends of grace periods. We therefore dispense with `rcu_check_callbacks()` (Section 3.5.1). Instead, we directly call `rcu_note_context_switch()` just after releasing a CPU, which in turn calls `rcu_sched_qs()` to record the quiescent state. Finally, we call `rcu_process_callbacks()`, which notes grace-period beginnings and ends and reports quiescent states up RCU's combining tree.

Grace-Period Kthread

As discussed in Section 3.5.2, `rcu_gp_kthread()` invokes `rcu_gp_init()`, `rcu_gp_fqs()`, and `rcu_gp_cleanup()` to initialize, wait for, and clean up after each grace period, respectively. To reduce the size of the formula generated by CBMC, instead of spawning a separate thread, we directly call `rcu_gp_init()` from `rcu_spawn_gp_kthread` and `rcu_gp_cleanup()` from `rcu_report_qs_rsp()`. Because we model neither idle nor usermode execution, we need not call `rcu_gp_fqs()`.

Kernel Spin Locks

CBMC's `__CPROVER_atomic_begin()`, `__CPROVER_atomic_end()`, and `__CPROVER_assume()` built-in primitives are used to construct atomic test-and-set for `spinlock_t` and `raw_spinlock_t` acquisition and atomic reset for release. We use GCC atomic builtins for user-space execution: `while (__sync_lock_test_and_set(lock, 1))` acquires a lock and `__sync_lock_release(lock)` releases it.

Limitations

We model only the fundamental components of Tree RCU, excluding, for example, quiescent-state forcing, grace-period expediting, and callback handling. In addition, we make the assumption that all CPUs are busy executing RCU related tasks. As a result, we do not model the following scenarios: 1. CPU hotplug and dyntick-idle; 2. Thread-migration failure modes in the Linux kernel involving per-CPU variables; 3. RCU priority boosting. Moreover, we model scheduling-clock interrupts as direct function calls, which, as discussed later, results in failures to model one of the bug-injection scenarios. Lastly, the test harness we use only passes through a single grace period, so cannot detect failures involving multiple grace periods.

6. Experiments

In this section we discuss our experiments verifying the Linux-kernel Tree RCU implementation. We first describe several bug-injection scenarios used in the experiments. Next, we report results of user-space runs of the RCU model. Then we describe how verify our RCU model using CBMC. Finally, we discuss the experimental results. We performed our experiments on a 64-bit machine running Linux 3.19.8 with eight Intel Xeon 3.07 GHz cores and 48 GB of memory.

6.1 Bug-Injection Scenarios

Because we model non-preemptible Tree RCU, each CPU runs exactly one RCU task as a separate thread. Upon completion, each task increments a global counter `thread_cnt`, enabling the parent thread to verify the completion of all RCU tasks using a statement `__CPROVER_assume(thread_cnt == 2)`. The base case uses the example in Figure 2, including its assertion `assert(r2 == 0 || r1 == 1)`. This assertion does not hold when RCU's fundamental safety guarantee is violated: read-side critical sections cannot span grace periods [**?**]. We also verify a *weak form* of liveness by inserting an `assert(0)` after the `__CPROVER_assume(thread_cnt == 2)` statement. This assertion cannot hold, and so it will be violated if at least one grace period completes. Such a "verification failure"is in fact the expected behavior for a correct RCU implementation. On the other hand, if the assertion is not violated, grace periods never complete, which indicates a liveness bug.

To validate our verification, we also run CBMC with the bug-injection scenarios described below,[4] which are simplified versions of bugs encountered in actual practice. Bugs 2–6 are liveness checks and thus use the aforementioned `assert(0)`, and the remaining scenarios are safety checks which thus use the base-case assertion in Figure 2.

Bug 1 This bug-injection scenario makes the RCU update-side primitive `synchronize_rcu()` return immediately (line 523 in `tree_plugin.h`). With this injected bug, updaters never wait for readers, which should result in a safety violation, thus preventing Figure 2's assertion from holding.

[4] Source code is available: `http://lxr.free-electrons.com/source/kernel/rcu/?v=4.3`

Bug 2 The key idea behind this bug-injection scenario is to prevent individual CPUs from realizing that quiescent states are needed, thus preventing them from recording quiescent states. As a result, it prevents grace periods from completing. Specifically, in function `rcu_gp_init()`, for each `rcu_node` structure in the combining tree, we set the field `rnp->qsmask` to 0 instead of `rnp->qsmaskinit` (line 1889 in `tree.c`). Then when `rcu_process_callbacks()` is called, `rcu_check_quiescent_state()` will invoke `__note_gp_changes()` that sets `rdp->qs_pending` to 0. Thus, `rcu_check_quiescent_state()` will return without calling `rcu_report_qs_rdp()`, preventing grace periods from completing. This liveness violation should fail to trigger a violation of the end-of-execution `assert(0)`.

Bug 3 This bug-injection scenario is a variation of Bug 2, in which each CPU remains aware that quiescent states are required, but incorrectly believes that it has already reported a quiescent state for the current grace period. To accomplish this, in `__note_gp_changes()`, we clear `rnp->qsmask` by adding a statement `rnp->qsmask &= ~rdp->grpmask;` in the last **`if`** code block (line 1739 in `tree.c`). Then function `rcu_report_qs_rnp()` never walks up the `rcu_node` tree, resulting in a liveness violation as in Bug 2.

Bug 4 This bug-injection scenario is an alternative code change that gets the same effect as does Bug 2. For this alternative, in `__note_gp_changes()`, we set the `rdp->qs_pending` field to 0 directly (line 1749 in `tree.c`). This is a variant of Bug 2 and thus also a liveness violation.

Bug 5 In this bug-injection scenario, CPUs remain aware of the need for quiescent states. However, CPUs are prevented from recording their quiescent states, thus preventing grace periods from ever completing. To accomplish this, we modify function `rcu_sched_qs()` to return immediately (line 246 in `tree.c`), so that quiescent states are not recorded. Grace periods therefore never complete, which constitutes a liveness violation similar to Bug 2.

Bug 6 In this bug-injection scenario, CPUs are aware of the need for quiescent states, and they also record them locally. However, they are prevented from reporting them up the `rcu_node` tree, which again prevents grace periods from ever completing. This bug modifies function `rcu_report_qs_rnp()` to return immediately (line 2227 in `tree.c`). This prevents RCU from walking up the `rcu_node` tree, thus preventing grace periods from ending. This is again a liveness violation similar to Bug 2.

Bug 7 Where Bug 6 prevents quiescent states from being reported up the `rcu_node` tree, this bug-injection scenario causes quiescent states to be reported up the tree prematurely, before all the CPUs covered by a given subtree

have all reported quiescent states. To this end, in `rcu_report_qs_rnp()`, we remove the **`if`**-block checking for `rnp->qsmask != 0 || rcu_preempt_blocked_readers_cgp(rnp)` (line 2251 in `tree.c`). Then the tree-walking process will not stop until it reaches the root, resulting in too-short grace periods. This is therefore a safety violation similar to Bug 1.
Bugs 2 and 3 would result in a too-short grace period given quiescent-state forcing, but such forcing falls outside the scope of this paper.

6.2 Validating the RCU Model in User-Space

To validate our RCU model before performing verification using CBMC, we executed it in user space. We performed 1000 runs for each scenario in Section 6.1 using a 60 s timeout to wait for the end of a grace period and a random delay between 0 to 1 s in the RCU reader task.

The results are reported in Table 1. Column 1 gives the verification scenarios. Scenario Prove tests our RCU model without bug injection. Scenario Prove-GP tests a weak form of liveness by replacing Figure 2's assertion with `assert(0)` as described in Section 6.1. The next three columns present the number and the percentage of successful, failing, and timeout runs, respectively. The following two columns give the maximum memory consumption and the total runtime. The last column explains the results.

As expected, for scenario Prove, the user program ran to completion successfully in all runs. For Prove-GP, it was able to detect the end of a grace period by triggering an assertion violation in all the runs. For Bug 1, an assertion violation was triggered in 559 out of 1000 runs. For Bugs 2–6, the user program timed out in all the runs, thus a grace period did not complete. For Bug 7 with one reader thread, the testing harness failed to trigger an assertion violation. However, we were able to observe a failure in 242 out of 1000 runs with two reader threads.

6.3 Getting CBMC to work on Tree RCU

We have found that getting CBMC to work on our RCU model is non-trivial due to Tree RCU's complexity combined with CBMC's bit-precise verification. In fact, early attempts resulted in SAT formulas that were so large that CBMC ran out of memory. After the optimizations described in the remainder of this section, the largest formula contained around 90 million variables and 450 million clauses, which enabled CBMC to run to completion.

First, instead of placing the scheduling-clock interrupt in its own thread, we invoke functions `rcu_note_context_`**`switch`**`()` and `rcu_process_callbacks()` directly, as described in Section 5. Also, we invoke `__note_gp_changes()` from `rcu_gp_init()` to notify each CPU of a new grace period, instead of invoking `rcu_process_callbacks()`.

Second, the support for linked lists in CBMC version 5.4 is limited, resulting in unreachable code in CBMC's symbolic execution. Thus, we stubbed all the list-related code in our RCU model, including those for callback handling.

Third, CBMC's structure-pointer and array encodings result in large formulas and long formula-generation times. Our focus on the RCU-sched flavor allowed us to eliminate RCU-BH's data structures and trivialize the **`for`**`_each_rcu_flavor()` flavor-traversal loops. Our focus on small numbers of CPUs meant that RCU-sched's `rcu_node` tree contained only a root node, so we also trivialized the `rcu_`**`for`**`_each_node_breadth_first()` loops traversing this tree.

Fourth, CBMC unwinds each loop to the depth specified in its command line option `--unwind`, even when the actual loop depth is smaller. This unnecessarily increases formula size, especially for loops containing intricate RCU code. Since loops in our model can be decided at compile time, we therefore used the command line option `--unwindset` to specify unwinding depths for each individual loop.

Finally, since our test harness only requires one `rcu_node` structure and two `rcu_data` structures, we can use 32-bit encodings for **`int`**, **`long`**, and pointers by using the command line option `--ILP32`. This reduces CBMC's formula size by half compared to the 64-bit default.

6.4 Results and Discussion

Table 2 presents the results of our experiments applying CBMC version 5.4 to verify our RCU model. Scenario Prove verifies our RCU model without bug injection over Sequential Consistency (SC). We also exercise the model over the weak memory models TSO and PSO in scenarios Prove-TSO and Prove-PSO, respectively. Scenario Prove-GP performs the same reachability check as in Section 6.2 over SC. We perform the same reachability verification over TSO and PSO in scenarios Prove-GP-TSO and Prove-GP-PSO, respectively. Scenarios Bug 1–7 are the bug-injection scenarios discussed in Section 6.1, and are verified over SC, TSO and PSO. Columns 2–4 give the number of constraints (symbolic program expressions and partial orders), variables, and clauses of the generated formula. The next three columns give the maximum (virtual) memory consumption, solver runtime, and total runtime of our experiments. The final column gives the verification result.

Since Tree RCU's implementation in the Linux kernel is sophisticated, its test suite is non-trivial [**?**], comprising several thousand lines of code. Therefore, it comes as little surprise that its verification is challenging.

In our experiments, CBMC returned all the expected results except for Bug 7, for which it failed to report a violation of the assertion `assert(r2 == 0 || r1 == 1)` with one RCU reader thread running over SC. This failure was due to the approximation of the scheduling-clock interrupt by a direct function call, as described in Section 5. However, CBMC did report a violation of

* This experiment was performed on a 64-bit machine running Linux 3.19.8 with twelve Intel Xeon 2.40 GHz cores and 96 GB of main memory

Таблица 2: Experimental Results of CBMC

the assertion either when two RCU reader threads were present or when run over TSO or PSO. All of these cases decrease determinism, which in turn more faithfully model non-deterministic scheduling-clock interrupts, allowing the assertion to be violated.

CBMC took more than 9 hours to verify our model over SC (scenario Prove). The resulting SAT formulas have more than 5m constraints, 30m variables and 149m clauses, and occupy 23 GB of memory. The formulas for scenarios Prove-TSO and Prove-PSO are about 40% larger than the scenario Prove. They have more than 40m variables and 200m clauses, and took more than 11 hours and 33 GB memory to solve. Although this verification consumed considerable memory and CPU, it verified all possible executions and reorderings permitted by TSO and PSO, a tiny subset of which are reached by the `rcutorture` test suite.

CBMC proved that grace periods can end (i.e., `assert(0)` is violated), over SC (Prove-GP), TSO (Prove-GP-TSO), and PSO (Prove-GP-PSO). The sizes of resulting formulas

Рис. 10: Total Runtime in Seconds

and memory consumption are similar to those of the three Prove scenarios. However, it took CBMC only about 4, 13, and 8.5 hours to find an violation of `assert(0)` in Prove-GP, Prove-GP-TSO, and Prove-GP-PSO, respectively.

For the bug-injection scenarios described in Section 6.1, CBMC was able to return the expected results in all scenarios over SC except for Bug 7, as noted earlier. The formula size varies from scenarios to scenarios, with 27m–35m variables and 138m–174m clauses. The runtime was 4–9 hours and memory consumption exceeded 22 GB. The exceptions are Bugs 1 and 6, which have fewer than 14m variables and 64m clauses, and took less than 35 mins and about 9 GB of memory to solve. This reduction was due to the large amount of code removed by the bug injections in these scenarios.

Figures 7–8 compare the formula size between SC, TSO and TSO. Comparison of runtime and memory can be found in Figures 10 and 11. As we can see, the runtime and memory overhead for the TSO and PSO variants of a given experiment are quite similar. The overheads of TSO are slightly higher than those of PSO in all bug-injection scenarios except for Bug 7 on which PSO had longer runtime. However, the overhead of TSO and PSO is significantly larger than that of SC, with up to 340% (Bug 6 runtime) and 50% (Bug 1 memory) increases. The runtime was 5–19 hours and memory consumption exceeded 31 GB in all scenarios except Bug 1 and 6. The

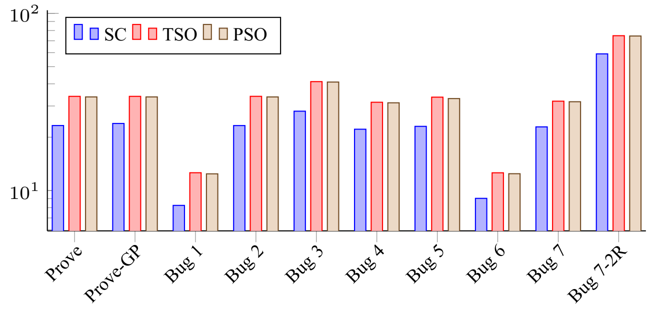

Рис. 11: Maximum Memory Consumption in Gigabytes

numbers of variables and clauses are 37m–49m and 188m–245m, respectively, around 130% greater than SC.

The two-reader variant of Bug 7 has by far the longest runtime, consuming more than 19 hours and 78 hours over SC and TSO, respectively, comparing to 9 hours and 11 hours with one reader. It also consumed about 75 GB memory, more than double the one-reader variant. For PSO, with two reader threads CBMC's solver ran out of memory after 85 hours whereas with one reader it completed in less than 12 hours. The increased overhead is due to the additional RCU reader's call to `rcu_process_callbacks()`. This in turn results in more than a 125% increase in the number of constraints, variables, and clauses. For example, the two-reader TSO formula has triple the constraints and double the variables and clauses of the one-reader case.

7. Related Work

McKenney applied the SPIN model checker to verify RCU's `NO_HZ_FULL_SYSIDLE` functionality [**?**], and interactions between dyntick-idle and non-maskable interrupts [**?**]. Desnoyers et al. [**?**] propose a virtual architecture to model out-of-order memory accesses and instruction scheduling. User-level RCU [**?**] is modeled and verified in the proposed architecture using the SPIN model checker.

These efforts require an error-prone translation from C to SPIN's modeling language, and therefore are not appropriate for regression testing. By contrast, our work constructs an RCU model directly from its source code from the Linux kernel, and verifies it using automated verification tool.

Alglave et al. [**?**] introduce a symbolic encoding for verifying concurrent software over a range of memory models including SC, TSO and PSO. They implement the encoding in the CBMC bounded model checker and use the tool to verify `rcu_assign_pointer()` and `rcu_dereference()`.

McKenney used CBMC to verify Tiny RCU [**?**], a trivial Linux-kernel RCU implementation for uni-core systems.

Groce et al. [**?**] introduce a falsification-driven verification methodology that is based on a variation of mutation testing. By using CBMC, they were able to find two holes in `rcutorture`–RCU's stress testing suite, one of which was hiding a real bug in Tiny RCU. Further work on real hardware identified two more `rcutorture` holes, one of which was hiding a real bug in Tasks RCU [**?**] and the other of which was hiding a minor performance bug in Tree RCU.

In this work, we use CBMC to verify the implementation of Linux-kernel Tree RCU for multi-core systems, which is more complex and sophisticated, over SC, TSO, and PSO.

Gotsman et al. [**?**] use a extended concurrent separation logic to formalise the concept of grace period and prove an abstract implementation of RCU over SC. Tassarotti et al. [**?**] use GPS, a recently developed program logic for the C/C++11 memory model, to carry out a formal proof of a simple implementation of user-level RCU for a singly-linked list assuming "release-acquire" semantics, which is weaker than SC but stronger than memory models used by real-world RCU implementations. These formal proofs were performed manually on simple implementations of RCU. By contrast, our work applies an automated verification tool with a test harness to verify the grace-period property of a real-world implementation of RCU over SC, TSO, and PSO.

Formal verification has started to make its way into real-world practice of verifying large non-trivial code bases. Calcagno et al. [**?**] describe integrating a static-analysis tool into Facebook's software development cycle. We believe that our work is an important step towards integration of verification into Linux-kernel RCU's regression test suite.

8. Conclusion

This paper overviews the implementation of Tree RCU in the Linux Kernel, and describes how to construct a model directly from its source code. It then shows how to use the CBMC model checker to verify a significant part of the Tree RCU implementation automatically, which to the best of our knowledge is unprecedented. This work demonstrates that RCU is a rich example to drive research: it is small enough to provide models that can just barely be verified by existing tools, but it also has sufficient concurrency and complexity to drive significant advances in techniques and tooling.

For future work, we plan to add quiescent-state forcing and grace-period expediting into our model and verify their safety and liveness properties, using more sophisticated test harnesses that pass through multiple grace periods and operate on a larger tree structure. We also plan to model and verify the preemptible version of Tree RCU, which we expect to be quite challenging. Moreover, there is much fertile ground verifying uses of RCU in the Linux kernel, for example, the Virtual File System (VFS).

There are also potential improvements for CBMC to better support future RCU verification efforts. For instance, better support of lists is required to verify RCU's callback handling mechanism. A field-sensitive SSA encoding for structures and a thread-aware slicer will help reduce encoding size, and therefore improve scalability.

This work demonstrates the nascent ability of SAT-based formal-verification tools to handle real-world production-quality synchronization primitives, as exemplified by Linux-kernel Tree RCU on weakly ordered TSO and PSO systems. Although modeling weak ordering incurs a significant performance penalty, this penalty is not excessive. We therefore hypothesize that use of these tools for highly concurrent multithreaded software will reach mainstream within 3-5 years, especially given recent rates of improvement.
